

Synchronized phenological dynamics of species communities

Journal:	<i>Ecology Letters</i>
Manuscript ID	ELE-00330-2017
Manuscript Type:	Letters
Date Submitted by the Author:	30-Mar-2017
Complete List of Authors:	<p>Delgado, Maria del Mar; Universidad de Oviedo, Research Unit of Biodiversity Tikhonov, Gleb; University of Helsinki Meyke, Evgeniy ; EarthCape OY Lo, Coong; University of Helsinki Gurarie, Eliezer; University of Maryland, Department of Biology Abadonova, Marina; National Park "Orlovskoe Polesie" Andreeva, Elena; State Nature Reserve Stolby Babushkin, Miroslav; Darwin Nature Biosphere Reserve Bakin, Oleg; Volzhsko-Kamsky National Nature Biosphere Reserve Basilskaja, Inna; Voronezhsky Nature Biosphere Reserve Belova, Nina; Baikalsky State Nature Biosphere Reserve Belyaeva, Natalia; Visimsky Nature Biosphere Reserve Beshkarev, Aleksandr; Pechoro-Ilych State Nature Reserve Bespalova, Tatjana; Kondinskie Lakes National Park Bobretsov, Anatoly; Pechoro-Ilych State Nature Reserve Bobrov, Vladimir; A.N.Severtsov Institute of Ecology and Evolution Bochkareva, Elena; Tigirek State Nature Reserve Bondarchuk, Svetlana; Sikhote-Alin State Nature Biosphere Reserve named after K.G. Statement of authorship: The data were collected by Russian co-authors. J.K. contributed in the dataset compilation and in the establishment and coordination of collaborations. E.M. and C.L. contributed to data management and preparation. M.M.D. and O.O. conceived the idea and wrote the paper; G.T. performed analyses. All authors provided useful comments on earlier drafts

Data accessibility statement: We confirm that, should the manuscript be accepted, the data supporting the results will be achieved in a public repository, and the data DOI will be included at the end of the article.

1 Abstract

2 Phenological changes evidence that species are responding to climate change, yet the spatial
3 variation of phenological responses at large scale is not well known. Such knowledge would be
4 crucial for obtaining a comprehensive understanding of the consequences of climate change to
5 species communities. By utilizing an extensive (ca. 116,000 dates) large-scale (239 localities in
6 Russia) and long-term (1960-2014) multi-taxon (plants, birds, insects, amphibians, reptiles and
7 fungi) database, we identified a bimodal geographical pattern in phenological responses, with some
8 events advancing in the north but delaying in the south, whereas others advancing both in north
9 and south. For particular events, phenological shifts were consistent among species but markedly
10 varied among sites, suggesting a strong influence of local conditions. Variation in spring phenology
11 was correlated with temperature for species groups other than birds, with uniform sensitivity to
12 temperature throughout the geographical gradient. Our results notably demonstrate that
13 phenological dynamics of multiple species can be synchronised by climate change over broad
14 distances.

15
16 Keywords: global warming | Moran effect | synchronous community | spatial variability
17

1 Introduction

2 Phenological dynamics have been recognised as one of the most reliable bio-indicators of species
3 responses to ongoing warming conditions (Post *et al.* 2001). Together with other adaptive mechanisms,
4 such as changes in spatial distribution and physiological adaptations, phenological plasticity is a key
5 adaptive response for maintaining many aspects of biodiversity in a changing world (Koh *et al.* 2004;
6 Bellard *et al.* 2012).

7 Many studies have documented that in the northern hemisphere spring events are becoming earlier
8 whereas autumn events are occurring later, mostly due to raising temperatures (Parmesan & Yohe 2003;
9 Root *et al.* 2003). Despite this broad unanimity, there is abundant evidence suggesting that there are
10 systematic differences in phenological responses to climate change among individual species (Parmesan
11 2007; Both *et al.* 2009; Cook *et al.* 2012), different taxonomic groups or trophic levels (Voigt *et al.* 2003;
12 Thackeray *et al.* 2010; Thackeray *et al.* 2016). Species-specific responses to climate change can create
13 mismatches between species (e.g. Harrington *et al.* 1999; Visser & Both 2005) and potentially affect
14 community persistence. Yet, up to date there has been a lack of consensus on which species are showing
15 most, and which are showing least, changes. To realistically assess the extent to which the stability and
16 persistence of natural systems will be hampered due to loss of phenological synchrony, we need to go
17 beyond simply reporting correlations between temperature and dates of phenological events, and build
18 models studying the drivers of the dynamics of populations and communities facing global change. For
19 example, Ovaskainen *et al.* (2013) demonstrated that even if many species are shifting at different rates,
20 synchronous species tend to shift in congruence. This result suggests that climate change may disrupt
21 community-level synchrony less than what was assumed in earlier studies. Unfortunately, this positive
22 finding may be only part of the story. Their study was performed using long-term data that was
23 systematically collected on many taxonomic groups and on many kinds of weather events, but only in
24 one locality. Climate is, however, changing in a multidimensional fashion, so it is not only shifting in time
25 but creating unpredictable new environmental conditions that may vary with latitude (Root *et al.* 2003;
26 Menzel *et al.* 2006b; Doi & Takahashi 2008). Few studies analysing geographically extensive datasets
27 have observe that temporal trends in phenological response vary spatially (e.g. Root *et al.* 2003; Menzel
28 *et al.* 2006b; Rubolini *et al.* 2007; Hurlbert & Liang 2012), yet the latitudinal trends are still unclear. For
29 example, while Menzel *et al.* (2006b) suggested a weaker phenological responses in plant to temperature
30 at high latitudes compared to those found in warmer countries, Root *et al.* (2003) observed the opposite
31 patterns.

32 To examine to what extent the mechanisms triggering phenological events vary in time (Ovaskainen *et al.*
33 2013) and over space (e.g. Menzel *et al.* 2006b; Primack *et al.* 2009), a comprehensive understanding of
34 phenological responses to climate change requires community-wide data that are both long-term and
35 spatially extensive (Doi & Takahashi 2008). Such data are still not common and, with few exceptions (Doi
36 & Takahashi 2008; Primack *et al.* 2009; Thackeray *et al.* 2010), the assessments of broad-scale taxonomic
37 and geographic variations in phenological changes have generally involved meta-analyses (Root *et al.*

1
2 1 2003; Ge *et al.* 2015), or analyses of large observational databases that either represent mid-latitude
3 2 systems (e.g. Walther *et al.* 2002; Parmesan & Yohe 2003; Root *et al.* 2003) or are characterized by low
4 3 species richness (Menzel *et al.* 2006a). Therefore, the spatial variation in phenological dynamics of
5 4 species communities at large scale is still not well known (Menzel *et al.* 2006a; Doi & Takahashi 2008).
6 5 Yet, this information is essential for understanding how species and communities response to climate
7 6 change (Roy *et al.* 2015).

8 7 The hypothesis that spatially-separated animal and plant populations may be synchronized, i.e.
9 8 experiencing concurrent fluctuations over time, by climate is highly relevant because it suggests that
10 9 local populations can be similarly influenced over broad distances by ongoing warming conditions (Post &
11 10 Forchhammer 2002, 2004). Population synchrony has been so far mostly studied from the point of view
12 11 of variations in density dependent characteristics (e.g. population abundance) within a single species or
13 12 among a few interacting species (Hansen *et al.* 2013). In many systems, the strength of synchrony
14 13 declines monotonically with increasing distance between populations, although more complex patterns
15 14 are also possible (Ranta *et al.* 1997; Koenig 1999; Liebhold *et al.* 2004). Efforts to attribute synchronous
16 15 fluctuations of contiguous populations to climate are, however, confounded by the synchronizing
17 16 influences of dispersal and ecological interactions (Heino *et al.* 1997; Liebhold *et al.* 2004). Thus, the
18 17 potentially synchronising role of climate may be more effectively assessed through processes that
19 18 respond to climate more directly than abundance, such as phenology. As phenological events can be
20 19 synchronised in the same way as population fluctuations (Ranta *et al.* 2010), assessing the spatial scale of
21 20 phenological synchrony among different species (Hansen *et al.* 2013) may be crucial for predicting the
22 21 large-scale consequences of climate change in ecological communities.

23 22 Our aim is to utilize a large-scale and long-term dataset to examine two major axes related with
24 23 community-level spatial variation in phenological dynamics and its climatic drivers: the spatial and
25 24 interspecific variability in phenological responses to climate change and the synchronizing effect of
26 25 climate at the ecological community level. Specifically, we asked (i) whether phenological events have
27 26 responded systematically to climate change over a broad geographical range, (ii) whether the responses
28 27 are consistent among species (or higher level units of taxa) or if different species show idiosyncratic
29 28 phenological trends, and (iii) whether spatial correlations in climate is enforcing synchronous community-
30 29 level phenological responses. Based on previous studies, we hypothesize that if geographic variation in
31 30 phenology reflects adaptation of the local climate, allowing species to track spatial and temporal
32 31 variation of environmental conditions, we should then expect to find differences in latitudinal patterns of
33 32 phenological response to changes in climatic conditions (Doi & Takahashi 2008). Even though different
34 33 species may respond individualistically to climate (Cleland *et al.* 2006), synchronous species among
35 34 populations may evolve similar phenological responses to environmental cues (Ovaskainen *et al.* 2013).
36 35 Thus, we expect that different phenological events, even across species and higher taxa may be
37 36 synchronized over long distances due to climatic conditions (Koenig 1999; Ranta *et al.* 2010; Hansen *et al.*
38 37 2013).

1

2 **Material and methods**

3 *Phenology and climate data*

4 The original dataset consisted of 241,225 observation dates collected in 239 localities in Russia, Ukraine,
5 Belarus, Latvia, Lithuania and Estonia (Fig. 1) during 115-year period (from 1899 to 2014). During this
6 period researchers intensively conducted regular observations to record dates at which a predefined list
7 of phenological and weather-related events occurred (Table 1). Yet, in order to perform comparable
8 analysis among the sites, we only used data from 1960 onwards (i.e. a 55-year-long time series from
9 1960 to 2014), which included 94% of the original number of observations. We only used the best
10 recorded phenological events (i.e. the ones we had the longest time series over the largest geographical
11 area) and grouped them into 14 classes (Table 1). The data used in this study consisted of 116,291 dates
12 representing 13,094 weather-related observations and 103,197 phenological observations. Events
13 measured for plants (trees, shrubs and grasses) include e.g. the onset days of leaf unfolding and leaf fall;
14 for birds (both resident and migratory species) they include e.g. days for first spring and last autumn
15 occurrences; for insects, amphibians, reptiles and fungi they include e.g. day of first occurrence in the
16 spring. The plant data were acquired in fixed plots, and the bird data along established routes. Weather-
17 related events were recorded as calendar dates when those events took place. We classified the
18 weather-related events into three groups: events related to temperature (e.g. the first day when
19 temperature crosses, for instance, -5°C), snow (e.g. the day of first winter snowfall) and ice (e.g. the first
20 winter day with ice on ponds). The 84.6% of the phenological dates were collected by research personnel
21 of nature protected areas and national parks, who followed a systematic protocol with sampling effort
22 remaining nearly constant. The remaining 15.4% of the observations came from a well-established
23 phenological network of volunteers, who notably also followed similar systematic protocol. In addition,
24 we used three weather covariates, namely mean temperature, precipitation and snow cover, which were
25 daily collected in a large network of meteorological stations located through Russia, Ukraine, Belarus and
26 Kazakhstan (All-Russia Research Institute of Hydrometeorological Information - World Data Centre
27 RIHMI-WDC). The study area has experienced an overall increase in temperature (on average $+0.03^{\circ}\text{C}$
28 year^{-1} ; Fig. 1B), in precipitation (on average $+0.6 \text{ mm year}^{-1}$; Supplementary Information I Fig. S1) and in
29 snowfall (on average $+0.04 \text{ cm year}^{-1}$; Supplementary Information I Fig. S1).

30 Additional information of the structure of the data (i.e. the representation of species and time periods
31 across the sites) can be found in Supplementary Information I Fig. S2 and Supplementary Information II
32 Table S1.

33 *Statistical analyses*

34 We used linear mixed models to study how the mean timings and long-term shifts of the phenological
35 events and the weather events vary among the species and the sites. We built separate model for each
36 class of phenological and weather-related events listed in Table 1. In these models, the response variable

1
2 1 d_{sit} was the day when a particular event for the species i (or particular weather-event) happened in the
3 site s in the year t . We assumed a linear mixed model, which we write with the help of fixed (F) and
4 random (R) effects as
5
6

$$7 \quad d_{sit} = L_{sit}^F + L_{sit}^R + \varepsilon_{sit}, \quad [Eq. 1]$$

8
9 where $\varepsilon_{sit} \sim N(0, \sigma^2)$ is a normally distributed residual. The fixed effects L_{sit}^F include the linear effects of
10 the longitude x and latitude y of the site s , the year t , and their interactions:
11
12

$$13 \quad L_{sit}^F = \alpha + \beta_x x + \beta_y y + \beta_t t + \beta_{xt} xt + \beta_{yt} yt.$$

14
15 The random effects L_{sit}^R include the main effect of the site s (not explained by latitude and
16 longitude), main effect of the species (or weather-event) i , the interaction between these two, as
17 well as site- and species specific variation in the linear response to the year t :
18
19

$$20 \quad L_{sit}^R = a_s + b_i + c_s t + d_i t + e_{si}.$$

21
22 Each random term was assumed to be normally distributed with its factor-specific variance:
23
24

$$25 \quad a_s \sim N(0, \sigma_A^2), b_i \sim N(0, \sigma_B^2), c_s \sim N(0, \sigma_C^2), d_i \sim N(0, \sigma_D^2), e_{si} \sim N(0, \sigma_E^2).$$

26
27 We defined *shift* as the long-term change in a phenological or weather-related event, measured by
28 the slope of the linear regression of date explained by year. We defined *mean date* as the
29 prediction of the model for a reference year, set here to 1990, which year approximately
30 represents the mean year in our data. We partitioned the variation of mean dates and shifts for
31 each event by comparing the variances for different random effects (site, species, site-species
32 interaction) and the variance due to geographical gradient, calculated as sum of longitude and
33 latitude effects multiplied to the variances of corresponding predictors.
34
35
36

37
38 We estimated the geographical gradients for the mean date and the shift for each event by
39 considering the direction at which the values changed the most per unit distance based on the
40 fixed effect part of the model. For graphical representation of mean dates and shifts over the study
41 area, we used the model prediction based on both fixed and random effects, which prediction we
42 interpolated by ordinary kriging with constant mean field and variogram of Gaussian form
43 (Banerjee *et al.* 2004), fitted to empirical variogram of the mean dates and shifts at sites.
44
45
46

47
48 As the data from the Russian Far East were quite sparse (Fig. 1), we analysed the data for the
49 eastern sites (located to the east from 70-degree meridian) separately for each location by applying
50 the same model, but without terms related to the effect of the site s and its longitude x and
51 latitude y .
52
53

54
55 To study how the phenological variation correlates with weather variation, we modelled the
56 residual terms ε_{sit} further as a function of weather variables. We built three separate models, in
57 each of which we used one of the daily measured weather covariates (mean temperature,
58 precipitation and snow cover) as the predictor. We pre-processed the weather data to values w_{sit}
59
60

1 that described the weather conditions for site s and year t at the time of the year that was relevant
 2 for the phenological event for species i . To do so, we used piecewise linear interpolation of
 3 weather data recorded at meteorological stations as the proxy for weather conditions at each site
 4 s . We then removed a linear trend of year as we aimed w_{sit} to model year-to-year variation rather
 5 than a long-term shift. We defined w_{sit} as the average the weather data over the time period
 6 $(m_{is} - d_A, m_{is} + d_B)$, where m_{is} is the mean date of the focal phenological event for site s ,
 7 predicted by the Eq. 1 for year 1990, and d_A and d_B were the predefined parameters of $d_A = 60$
 8 days and $d_B = 7$ days. To test the sensitivity of the results to these choices, we also repeated the
 9 analyses with $d_A = 15$ days and $d_B = 7$ days. In addition, we studied the effect of weather
 10 covariates at a global spatial scale. Global weather covariates were estimated by averaging daily
 11 mean observations from all meteorological stations of our study area (located to the west from 70-
 12 degree east meridian).

13 We related the residual variation in phenological timings to variation in weather conditions by the
 14 linear models

$$\varepsilon_{sit} = \hat{L}_{sit}^F + \hat{L}_{sit}^R + \hat{\varepsilon}_{sit} \quad [Eq. 2]$$

15 where the fixed and random parts are defined as

$$\hat{L}_{sit}^F = \hat{\alpha} + \hat{\beta}_x x + \hat{\beta}_y y + \hat{\beta}_w w_{sit} + \hat{\beta}_{xw} x w_{sit} + \hat{\beta}_{yw} y w_{sit},$$

$$\hat{L}_{sit}^R = \hat{a}_s + \hat{b}_i + \hat{c}_{si} + \hat{d}_s w_{sit} + \hat{e}_i w_{sit} + \hat{f}_{si} w_{sit}.$$

16 As with the model of Eq. 1, each random term was assumed to be normally distributed with its
 17 factor-specific variance: $\hat{a}_s \sim N(0, \hat{\sigma}_A^2)$, $\hat{b}_i \sim N(0, \hat{\sigma}_B^2)$, $\hat{c}_{si} \sim N(0, \hat{\sigma}_C^2)$, $\hat{d}_s \sim N(0, \hat{\sigma}_D^2)$, $\hat{e}_i \sim N(0, \hat{\sigma}_E^2)$,
 18 $\hat{f}_{si} \sim N(0, \hat{\sigma}_F^2)$.

19 We used fitted results of Eq. 2 to calculate the proportion of the variance (measured as R-squared)
 20 of each phenological event explained by each weather covariate, and estimated the sensitivity (i.e.
 21 the variation of phenological response to weather covariate unit) among different species and sites
 22 for each phenological event.

23 Finally, to analyse spatial synchrony we computed the annual averaged residuals ε_{pst} for each
 24 phenological event p and each site s . For each pair of phenological events and each pair of sites we
 25 calculated the Pearson correlation $\rho_{s_1 s_2}$ among the residuals ε_{pst} over those $n_{s_1 s_2}$ years for which
 26 the residuals could be computed for both sites. For a given pair of events, we fitted the non-linear
 27 model

$$\rho_{s_1 s_2} = \rho_0 \exp(-d_{s_1 s_2} / \alpha) + \varepsilon_{s_1 s_2},$$

28 where $d_{s_1 s_2}$ is the distance between sites s_1 and s_2 , and residual term $\varepsilon_{s_1 s_2} \sim N(0, \frac{\sigma^2}{n_{s_1 s_2}})$, where we
 29 assumed the error term to decrease with the number $n_{s_1 s_2}$ of years for which we had data for both
 30 sites.

1 sites. In the model fit we restricted $0 \leq \rho_0 \leq 1$ and $\alpha > 0$. To analyze how pairs of phenological
2 events are synchronized at the zero distance we calculated the Pearson correlation coefficients
3 among the annual averaged residuals ε_{p_1st} and ε_{p_2st} of different phenological events p_1 and p_2
4 within a single site s and averaged the result over the sites s .

5 All models were fitted in R 3.1.3 statistical software (2015), using applied Bayesian statistics
6 methods implemented in RJAGS package (Plummer 2015). We performed our posterior sampling
7 by 4 chains for 10^5 iterations each, with additional 10% burn-in and thinning interval of 100. The
8 chains' convergence was checked with Gelman and Rubin's convergence diagnostic test (Gelman &
9 Donald 1992) which score was below 1.05 level for all fitted models. The posterior sampling
10 distribution was later used to acquire posterior mean values of parameters of interest, as well as
11 95% central Bayesian credibility intervals for them.

13 Results and Discussion

14 Spatial and interspecific variability in phenological responses to climate change

15 As elsewhere in the Northern hemisphere (Hopkins 1918; Schwartz 2013), in Russia the mean timings of
16 phenological and weather-related events in spring generally progress from the south to the north,
17 whereas in autumn they show the opposite spatial pattern (Fig. 1; Supplementary Information I Figs. S3
18 and S4). Less trivially, variation in both phenological (three out of 14 significantly; Supplementary
19 Information II Table S2) and weather-related (one out of six significantly; Supplementary Information II
20 Table S2) long-term shifts is also partly structured along a south-north gradient (Figs. 1-2; Supplementary
21 Information I Figs. S3 and S4). This is especially the case for taxonomical groups other than plants and
22 birds, for which the geographic gradient explains 31-47% of the variation in phenological trends (Fig. 2C;
23 Supplementary Information II Table S3). Out of the ten spring and summer phenological events, six have
24 shifted to earlier in the northern part and to later in the southern part of the study region (Fig 2A; Fig. 1D
25 shows such a geographical pattern in the shift for the first occurrence of insects; Supplementary
26 Information I Figs. S3 and S5 show the geographic patterns in shift for each phenological event), and four
27 have shifted consistently to earlier throughout the study region (Fig. 2A). Out of the four events of
28 autumn phenology, two have shifted evenly to earlier (Fig. 1F shows such a geographical pattern in the
29 shift for onset of autumn colouring of plants) and two to later (Fig. 2A).

30 Our results are in line with some previous studies reporting a latitudinal effect on phenological shift. For
31 example, the variability of the slopes for leaf colouring and leaf fall day in Japan was found to be greater
32 at lower than at higher latitudes (Doi & Takahashi 2008). Zheng *et al.* (2006) observed an advancing trend
33 consistently for seven spring phenophases for plants in the NE of China, and a delayed trend in the SW of
34 China. Similarly, Ge *et al.* (2015) found that the strength of spring/summer advancement and autumn
35 delay of woody plants in China from 1960s to 2000s was strong at high latitude, even though geographic

1 factors only explained respectively the 14% and 4% of the variance in phenological changes. Root *et al.*
2 (2003) found a stronger phenological shift in northern latitudes than in southern latitudes that was
3 consistent among different taxonomic groups, although Menzel *et al.* (2006b) suggested the opposite.
4 However, while earlier studies have generally reported a consistent change across different phenophases
5 and taxonomical groups, our findings suggest that latitudinal patterns of responses among different
6 phenological events may not necessary be consistent (Fig. 2A). The difference between our results and
7 the earlier results may be, at least partly, explained by the fact that geographical trends in phenology
8 variations have been generally studied for few phenological events in a single taxonomic group, mostly
9 being either plants (e.g. Menzel *et al.* 2006b; Zheng *et al.* 2006; Doi & Takahashi 2008; Ge *et al.* 2015) or
10 birds (e.g. Both & Visser 2001; Lukas & Marc 2003; Hurlbert & Liang 2012). These accounts attributed the
11 discrepancy in phenological shifts in response to climate change to population - and species-specific
12 aspects (Inouye *et al.* 2000; Both & Visser 2001; Gordo & Doi 2012). However, given the complex
13 physiological mechanisms underlying environmental sensitivity of different phenological events, it is
14 perhaps not surprising that our results show that different phenological events do not respond equally
15 along a geographical gradient (Wilczek *et al.* 2010).

16 Disparities in phenological responses across latitudes will certainly limit our ability to forecast future
17 responses to warming conditions. For example, as a consequence of the patterns we documented, in the
18 south, where some phenological events have shifted to earlier and some others have shifted to later (Fig.
19 2A), there is a higher potential for disruption of phenological synchrony (both among taxonomic groups
20 and among different life-history stages) than in the north, where most events (12 out of 14 groups) have
21 shifted to earlier. As examples of such disruptions (shown in more detail in Supplementary Information I
22 Fig. S5), the onset of budburst in the south has shifted to later but the onset of leaf fall has shifted to
23 earlier (Fig. 2A), shortening the length of the growing season which has been reported to be of great
24 ecological and biogeochemical importance (e.g. Ibañez *et al.* 2010). In both south and north, birds have
25 advanced their arrival time but delayed their autumn departure, thus prolonging the summer period
26 everywhere and correspondingly shortening the time allocated for migration and wintering. Just as it is
27 important to understand the relationship between phenology and organisms' life history (Forrest &
28 Miller-Rushing 2010), understanding whether the interplay among physiology and external
29 environmental factors controlling the timing of biological events vary along a geographical gradient is
30 essential in order to predict phenological responses to environmental change.

31 The patterns summarized in Fig. 2A average over variation among sites not explained by the geographical
32 gradient (Koh *et al.* 2004). In almost all taxonomical groups, we found phenological shifts to vary
33 markedly among sites (Fig. 2C; Supplementary Information II Table S4). This is especially the case for
34 autumn phenological events in plants, where the random effect of site explained 51-73% of the variation
35 (Supplementary Information II Table S3). Such phenological variation among populations is likely to
36 reflect the potential of local populations to track the optimum timing by responding directly to the
37 environment (i.e. phenotypic plasticity) or by natural selection increasing the frequency of alleles that

1
2 1 confer a local advantage (i.e. local adaptation, Phillimore *et al.* 2012). There is ample evidence that
3 2 populations within a species and even individuals from different populations experiencing different
4 3 environmental conditions often differ phenotypically and genetically. As phenological traits usually show
5 4 a very high level of heritability and high level of genetic variability within and among populations, they
6 5 have a strong adaptive nature (Chuine 2010). As an example, Roy *et al.* (2015) provided a multi-species
7 6 analysis to test the role of local adaptation in generating spatial and temporal patterns in butterfly mean
8 7 flight dates. They observed that, even though all butterfly species had a plastic response to temperature,
9 8 emergence dates were mostly synchronized among populations, suggesting local adaptation. As a further
10 9 example, (Thuiller *et al.* 2004) showed that species growing in similar regions had developed similar
11 10 phenologies. It is remarkable that, in line with these results, we found that for five out of ten spring and
12 11 summer phenological events, and for three out of four autumn phenological events, the effect of site
13 12 significantly explained more of the variation in the phenological shift than the combined effects of the
14 13 geographic gradient and the species (Supplementary Information II Table S5), suggesting a strong
15 14 contribution of local adaptation to phenology.

16 15 The patterns summarized in Fig. 2A average not only over variation in space but also over variation
17 16 among species within each taxonomic group (Koh *et al.* 2004). Much of the variation in the mean timing
18 17 of phenological events is explained by variation among species (Fig. 2B), which is expected to be the case
19 18 as species represented in e.g. the taxonomical group of plants involves some species that bloom in early
20 19 spring and other species that bloom in late spring. However, a strikingly small amount of variation in
21 20 phenological shift was attributed to variation among species (Fig. 2C; Supplementary Information II Table
22 21 S4 and S5). This is an important result, as it suggests that the results of Fig. 2A are highly robust in the
23 22 sense that, for each particular phenological event essentially all species within an entire taxonomic group
24 23 have shifted similarly. One exception is the first occurrence of reptiles, where different species showed
25 24 opposite phenological shifts (Supplementary Information II Table S1). Another exception is the last
26 25 occurrence of birds, where variation among bird species in phenological shift was partially explained by
27 26 different migration strategies (Supplementary Information I Fig. S6). In contrast to our findings, many
28 27 previous studies have reported dissimilar responses to climate change not only among taxonomical
29 28 groups but also among species within a taxonomical group, an observation which has been attributed to
30 29 differences in life-history parameters (Parmesan & Yohe 2003; Root *et al.* 2003; Menzel *et al.* 2006b;
31 30 Zheng *et al.* 2006; Minin & Voskova 2014; Thackeray *et al.* 2016). For example, while the majority of plant
32 31 species have been found to respond to warming springs with earlier flowering (Parmesan & Yohe 2003;
33 32 Menzel *et al.* 2006b; Wolkovich *et al.* 2012), a consistent subset has been reported to show the opposite
34 33 trend (Fitter & Fitter 2002; Menzel *et al.* 2006b), possibly related to variation among species on chilling
35 34 requirements to break dormancy (Korner & Basler 2010; Yu *et al.* 2010). In our data, the shifts in plant
36 35 spring phenology were outstandingly consistent among species even if the dataset consist of both early
37 36 and late spring bloomers. Thus, while many earlier studies have shown consistent shifts among
38 37 phenophases but contrasting shifts among species or major functional groups (Thackeray *et al.* 2010;
39 38 Thackeray *et al.* 2016), our result essentially show the opposite pattern. In line with our results, a recent

1 study (CaraDonna *et al.* 2014) on the flowering phenology of 121 plant species in the Colorado Rocky
2 Mountains (USA) showed that many species exhibit an inconsistent shift in the first, peak, and last dates
3 of this specific phenophase. Consistent with Ge *et al.* (2015), our results also suggest that a limited
4 number of taxonomic groups may generate a biased estimates of trends.

5

6 Phenological responses to climate factors

7 Variation in phenological shifts can be generated by differences in environmental sensitivity among
8 species as well variation across geographical gradients (Ge *et al.* 2015; Wang *et al.* 2015) within a species
9 (but see Vitasse *et al.* 2009). Climatic factors driving long-term phenological shifts are expected to be
10 correlated with climatic cues used by species to adjust their phenology to short-term variation in climatic
11 conditions (Charmantier *et al.* 2008). These cues can be partially identified by correlating year-to-year
12 variation in phenology with climatic variation (Koh *et al.* 2004). In line with previous studies in middle and
13 high latitudes (Zhang *et al.* 2004; Wang *et al.* 2015), we found that variation in phenological timing in
14 most events is highly correlated with temperature, but only moderately correlated with snow cover and
15 precipitation (Fig. 3A; Supplementary Information II Table S6). Spring events start generally earlier in
16 years with high temperatures, little precipitation, and early loss of snow cover (Fig. 3A). In our data,
17 plants, insects, amphibians and reptiles show higher sensitivity to temperature (i.e. change in number of
18 days per 1°C) than birds and fungi (Fig. 3B; Supplementary Information II Table S7). This indicates that
19 different taxa may respond diversely to per unit change in temperature which, as recently suggested by
20 Thackeray and colleagues (Thackeray *et al.* 2010; Thackeray *et al.* 2016), can potentially lead to temporal
21 mismatches in trophic interactions. While we found birds to respond more strongly to short-term climate
22 cues, plants were triggered by longer-term climatic averages (Supplementary Information I Fig. S7).
23 Further, phenological events correlated generally more with weather variables measured at local than
24 global spatial scales, suggesting the importance of local processes even for migratory birds
25 (Supplementary Information I Fig. S7). In contrast to other phenological events, plant phenology in the
26 autumn and the fruiting of fungi were only weakly correlated with any of the tested weather covariates
27 (Fig. 3A). This result is in line with earlier research suggesting that temperature is not likely to be the
28 dominant factor controlling autumn phenological trends (Matsumoto 2010; Gallinat *et al.* 2015).

29 Differences in environmental sensitivity among species as well as within species across geographical
30 gradients may hinder the effect of latitude on phenological responses to warming (Ge *et al.* 2015). While
31 some studies have shown that species inhabiting high latitudes are especially sensitive to thermal
32 variation in the environment (Wang *et al.* 2015), others have shown the opposite pattern (Menzel *et al.*
33 2006b; Ge *et al.* 2015; Wang *et al.* 2015). The species in our study appear to adjust their phenology to
34 temperature in a very consistent way across the entire study region (Fig. 3B). One explanation for the
35 dissimilarity to earlier results may be the fact that our data is characterized by a high species richness
36 covering a large geographic area compared to many earlier studies (e.g. Wang *et al.* 2015), and that the
37 data have been acquired and analysed in a consistent way (in contrast to meta-analyses), thus increasing

1
2 1 the signal to noise ratio.
3

4 2
5

6 3 **The synchronizing effect of climate at the ecological community level** 7

8 4 Many interspecific interactions depend upon the synchrony of phenological events, and thus decoupling
9
10 5 of phenological synchrony may have major consequences on community structure and functioning
11
12 6 (Gilman *et al.* 2010). Synchrony among phenological timing among species can be expected either if the
13
14 7 species respond to common environmental drivers or if the species have tight ecological interactions
15
16 8 (Liebhold *et al.* 2004). We found that synchrony was high among phenological events that were highly
17
18 9 correlated with temperature (e.g. spring phenological events of plants, amphibians, insects and reptiles;
19
20 10 Fig. 4A), lending support to the former view. In contrast, synchrony among birds, fungi and autumn
21
22 11 phenological events was generally low (Fig. 4A), which is in line with the fact that these groups were
23
24 12 weakly correlated with temperature and the other measured weather covariates (Fig. 3). For example,
25
26 13 autumn phenological events in plants are known to be modulated by multiple mechanisms, including leaf
27
28 14 structural constraints on longevity, several plant hormones and programmed cell death (Keenan &
29
30 15 Richardson 2015). Some previous studies have reported a relationship between irregularities in timing of
31
32 16 spring phenology and the leaf senescence, suggesting that the influence of temperature on leaf fall may
33
34 17 be offset by the influence of an earlier spring (Keenan & Richardson 2015). Yet, the influence of some
35
36 18 other less predictable factors on autumn phenology, such as soil humidity and wind (Gallinat *et al.* 2015),
37
38 19 may hinder the synchrony between spring and autumn timing in plants.
39

40 20 We found a negative relationship between phenological synchrony and distance, as has been found also
41
42 21 in previous studies (Koenig 1999). The spatial synchrony in spring plant phenology was high at short
43
44 22 distances (Fig. 4C), suggesting that the environmental factors driving phenological events in plants show
45
46 23 a more localized spatial autocorrelation. Further, the spatial synchrony in the arrival of birds was
47
48 24 somewhat lower at short distances but spanned over a larger spatial scale (Fig. 4D), likely due to the fact
49
50 25 that the breeding populations overlap in their wintering grounds and that migration is partly controlled
51
52 26 by photoperiod (Ramenofsky 2012). Interestingly, the level of spatial synchrony in birds drops
53
54 27 considerably from the onset of their arrival to the start of singing and display flights (Fig. 4D), suggesting
55
56 28 that the latter events are controlled by some idiosyncratic factors not considered here. Amphibians,
57
58 29 insects and reptiles also showed substantial spatial synchrony (Fig. 4E), whereas fungi and autumn
59
60 30 phenological events showed very little – consistent with the weaker responses of these groups to
31
32 31 temperature (Fig. 3). Variation in temperature was synchronized over much larger distances than
33
34 32 variation in phenological events (Fig. 4B), suggesting that the other factors that control phenological
35
36 33 dynamics are less correlated in space than temperature.

34 34 Many phenological events are closely associated with population growth (Post 2003; Ranta *et al.* 2010).
35
36 35 For example, the timing of flowering affects the success of fruit maturation, the quality of progeny and
37
38 36 the success of pollination (for review see Levin 2006). Thus the spatial scales of phenological synchrony

1 reported here can be expected to be related to the spatial scale of synchrony in population fluctuations
2 as well. Several authors have emphasized the need for understanding the drivers of the dynamics of
3 populations and communities facing global change rather than just reporting whether some phenological
4 events are advancing, delaying, or not changing through time (Heino *et al.* 1997; Ranta *et al.* 1997). We
5 have taken first steps in this direction by utilizing long-term and spatially extensive data to analyse the
6 community-level spatial synchrony in phenological dynamics and its climatic drivers.

1 Tables

2 **Table 1.** Summary of phenological and weather-related events recorded. For each event, values shown are the total number of observations (no), the
3 number of locations (Locations), the total number of species (Species) or climatic events, and the mean number of observations per location
4 (no/Location). The bars represent the timings of the events, ranging from the minimum to the maximum mean dates (mean date is represented by the
5 circle).

				Timing Julian dates																		
		Jan	Feb	March	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec									
		10 20	9 19	11 21	10 20	10 20	9 19	9 19	8 18	7 17	7 17	6 16	6 16									
		10 20	40 50	70 80	100	110	130	140	160	170	190	200	220	230	250	260	280	290	310	320	340	350
Events		no	Locations	Species	no/Location																	
BIRDS	1 st occurrence	19008	174	195	110																	
	1 st song	9214	176	88	53																	
	Last occurrence	1789	14	36	128																	
PLANTS	Onset of budburst	4269	16	117	267																	
	Onset of leaf unfolding	13872	206	153	68																	
	Onset of blooming	42798	220	505	195																	
	1 st ripe fruit or berries	10361	29	225	358																	
	Onset of autumn colouring	10513	161	133	66																	
	Onset of leaf fall	6768	55	127	124																	
	Leaf fall end	9407	192	110	49																	
INSECTS	1 st occurrence	5844	27	60	217																	
AMPHIBIANS	1 st occurrence	863	18	10	48

1 Figure legends

2 **Figure 1.** Examples of spatio-temporal patterns in climatic and phenological data. Panel **A** shows
 3 mean temperature over the study period 1960-2010, panel **B** the shift in mean temperature per
 4 decade, panels **CD** the relative mean day (centred on calendar day 125) and shift for the first
 5 occurrence of insects, and panels **EF** the relative mean day (centred on calendar day 244) and shift
 6 for the onset of autumn colouring of plants from 1960 to 2014 (Supplementary Figure 2 displays
 7 relative mean day and shift for each phenological and weather-related events analysed). The
 8 locations of the data sources are shown by the squares (black if a particular event was recorded,
 9 grey otherwise) and dots (meteorological stations). Stars on the latitude axis mark the selected
 10 latitudes of South (red) and North (blue) analysed in Fig. 2. Phenological mean dates and shift are
 11 interpolated over the western part of the study area with high density of observed locations and
 12 depicted for local neighbourhoods of sparse locations in the east.

13
 14 **Figure 2.** Spatio-temporal patterns in weather-related and phenological data. In panel **A** each event
 15 is located based on its shifts observed in the Northern and Southern parts of the study area
 16 (indicated by the stars in Fig. 1). Red and blue lines over the symbols of weather-related events
 17 indicate spring and autumn events respectively. Panels **BC** partition variation in mean timing (**B**)
 18 and shift (**C**) of phenological and weather-related events. The partitions have the following
 19 meaning: average shift (red and blue bars represent shift to earlier and later dates), variation due
 20 to species (orange) or weather-related group (brown), variation due to major linear geographic
 21 gradient (black), variation due to location (green) and the variation related to the interaction
 22 between species and location (white). Red, green and blue bars below the histogram represent
 23 respectively spring, summer and autumn phenological and weather-related events.

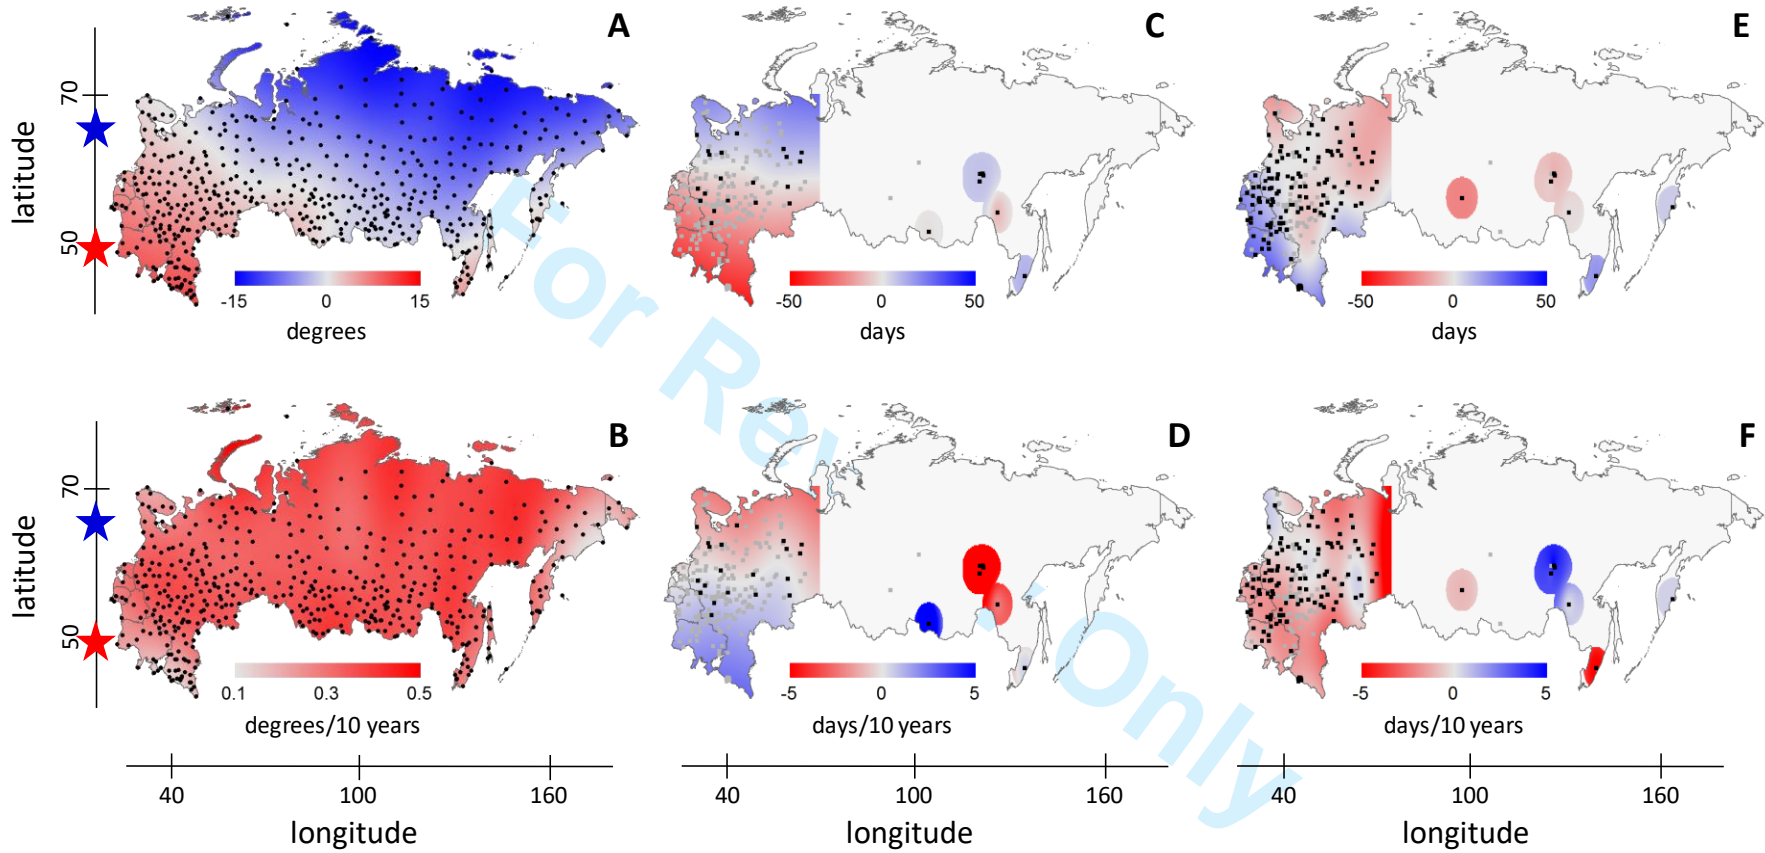

24
 25 **Figure 3.** Year-to-year variation in phenological timing explained by climatic factors. In panel **A** the
 26 solid bars show the Pearson correlation coefficient of phenological timing and local weather
 27 covariates, the latter averaged over the period from 60 days before to 7 days after the onset of
 28 phenological events. The edge of extended semi-transparent bar represents the square root of the
 29 R-squared for the corresponding hierarchical model. Dark and light colours respectively correspond
 30 to negative and positive correlations. Panel **B** partitions variation in response of phenological timing
 31 to temperature: average response (red and blue indicating negative or positive effects
 32 respectively), variation explained by species (orange), by geographic gradient (black), location
 33 (green) and the interaction between species and location (white). Red, green and blue bars in the
 34 bottom of the figure represent respectively spring, summer and autumn phenological events.

35
 36 **Figure 4.** Spatial synchrony among phenological and climatic events. Panel **A** shows the level of
 37 synchrony between events within the same locality with width of connecting curves representing
 38 the proportion between the number of localities where two corresponding events were
 39 synchronized and the number of localities where the two corresponding events were observed.
 40 Red, green and blue colours correspond to the mean timing of event: spring, summer and autumn,
 41 respectively. Panel **B** shows the synchrony of temperature (red) and precipitation (blue), averaged
 42 over Mar-Apr (solid) and Sep-Oct (dashed). Panels **CDE** show within-event phenological synchronies

1
2 1 as a function of distance between localities for events related to plants (C), birds (D), and other
3 2 phenological events (E). Solid lines stand for spring events, dotted for summer and dashed for
4 3 autumn.
